ABSTRACT

How important is an independent diameter measurement for the determination of stellar parameters of solar-type stars? When coupled with seismic observables, how well can we determine the stellar mass? If we can determine the radius of the star to between 1% and 4%, how does this affect the theoretical uncertainties? Interferometry can provide an independent radius determination and it has been suggested that we should expect at least a 4% precision on such a measurement for nearby solar-type stars. This study aims to provide both qualitative and quantitative answers to these questions for a star such as our Sun, where seismic information will be available. We show that the importance of an independent radius measurement depends on the combination of observables available *and* the size of the measurement errors. It is important for determining all stellar parameters and in particular the mass, where a good radius measurement can even allow us to determine the mass with a precision better than 2%. Our results also show that measuring the small frequency separation $\delta\nu$ significantly improves the determination of the evolutionary stage τ and the mixing-length parameter α .

Subject headings: stars: oscillations — stars: fundamental parameters (mass, age, initial hydrogen abundance, initial metal abundance, mixing-length parameter) — stars: interiors — methods: numerical — techniques: interferometric

1. INTRODUCTION

Asteroseismology is the interpretation of a star's oscillation frequency spectrum to characterize its internal structure. By probing its interior, we are testing our knowledge of fundamental physics. A star with oscillations such as our Sun (solar-type star) presents a frequency spectrum with a range of excited modes. Because most of the proper modes are excited, mode identification for each frequency is considerably easier than for other types of pulsating stars (Kjeldsen & Bedding 2004; Bedding et al. 2004; Kjeldsen et al. 2005).

Modelling these stars can be difficult as there are often multiple sets of parameters that fit the observations. Also, if we use the frequencies to determine the mass of the star, then any solution we find may be incorrect as it depends on the *fit* mass. If we could determine the mass of the star through some other means, then modelling the frequencies would be easier, *and* they could also then be used solely to characterize the internal structure of the star.

Unfortunately the precise determination of mass is normally possible only for detached components of similar mass in spectroscopic binary systems. For single stars we use observables such as magnitudes and colors (apart from oscillation frequencies) to estimate the mass. However, now that there

are various possibilities of measuring a radius for single stars through interferometry (Paresce et al. 2003; Glindemann et al. 2003; Kervella et al. 2003; Aufdenberg et al. 2006) the question then arises: Can radius be used to determine the mass of the star?

Recent studies have shown interferometry has determined the radius of a star with a precision of about 1% for the brightest stars and it has been suggested that we might obtain a precision of at least 4% for most nearby solar-type stars whose diameters we could expect to measure (Pijpers et al. 2003; Thévenin et al. 2005; Di Folco et al. 2004). Our interest is exploring how this independent measure complements oscillation frequency information for solar-type stars. Can it determine the mass of the star? And if so, can we then use the frequencies to probe the physics of the star? How important is the radius for determining other stellar parameters such as age and chemical composition? What is the impact on the expected uncertainties? Now that we are expecting frequency errors less than about $1.0\mu\text{Hz}$ with the launch of CoRoT⁸ (Baglin et al. 2000) and Kepler⁹ (Borucki et al. 1997, 2004; Basri 2004), does this have an effect on our results?

While the objective of this study is mainly to determine stellar mass, we also discuss results for other stellar parameters.

2. DESCRIPTION OF THE PROBLEM

2.1. Mathematical Solution

The techniques incorporated for this study follow that of Brown et al. (1994) and Miglio & Montalbán (2005). For a more elaborate description we refer the readers to Brown et al. (1994) or Press et al. (1992) and summarize here the main concepts for the purposes of understanding our work.

2.1.1. Finding the parameters

Taylor’s Theorem allows us to approximate any differentiable function near a point $\mathbf{x}_0$ by a polynomial that depends only on the derivatives of the function at that point. To first order this can be written as

$$\mathbf{f}(\mathbf{x}) = \mathbf{f}(\mathbf{x}_0) + \mathbf{f}'(\mathbf{x}_0)(\mathbf{x} - \mathbf{x}_0) \quad (1)$$

where $\mathbf{x} = \{x_j\}_{j=1}^N$ are the N parameters defining the system (“input parameters”) and $\mathbf{f} = \{f_i\}_{i=1}^M$ are the M expected outputs of the system that depend on $\mathbf{x}$. These are the expected measurements or *observables*. To distinguish between the expected observables and real observations we denote the latter by $\mathbf{O} = \{O_i\}_{i=1}^M$.

We measure $\mathbf{f}$ and would like to find the set $\mathbf{x}$ that produce these measurements. This problem is a typical inverse problem whose solution $\mathbf{x}$ (in the pure linear case) falls neatly out from

$$\mathbf{x} = \mathbf{x}_0 + \mathbf{V}\mathbf{W}^{-1}\mathbf{U}^T\delta\mathbf{f}, \quad (2)$$

where

$$\delta\mathbf{f} = \frac{\mathbf{O} - \mathbf{f}(\mathbf{x}_0)}{\epsilon}. \quad (3)$$

Here

$$\mathbf{f}'(\mathbf{x}_0)\epsilon^{-1} = \mathbf{D} = \mathbf{U}\mathbf{W}\mathbf{V}^T \quad (4)$$

is the *Singular Value Decomposition* (SVD) of the derivative matrix (section 2.1.2) and $\epsilon = \{\epsilon_i\}_{i=1}^M$ are the measurement errors.

In the case of a non-linear physical model, the method for finding the true values $\mathbf{x}$ is to use a modified version of equation (2) iteratively. Incorporating a goodness-of-fit test such as a χ^2 function

$$\chi^2 = \sum_{i=1}^M \frac{(f_i(\mathbf{x}) - O_i)^2}{\epsilon_i^2} \quad (5)$$

allows us to find the best set of parameters $\mathbf{x}$ by minimizing χ^2 .

There are many reliable algorithms available for performing such minimizations (Press et al. 1992). The algorithm implemented in this work is the *Levenberg-Marquardt* algorithm because it is known to be robust and incorporates derivative information. It also usually converges within 2-3 iterations to its minimum.

2.1.2. Singular Value Decomposition

SVD is the factorization of any $M \times N$ matrix $\mathbf{D}$ into 3 components $\mathbf{U}$, $\mathbf{V}^T$ and $\mathbf{W}$ (eq. (4)). $\mathbf{V}^T$ is the transpose of $\mathbf{V}$ which is an $N \times N$ orthogonal matrix that contains the *input* basis vectors for $\mathbf{D}$, or the vectors associated with the parameter space.

$\mathbf{U}$ is an $M \times N$ orthogonal matrix that contains the *output* basis vectors for $\mathbf{D}$, or the vectors associated with the observable space. $\mathbf{W}$ is a diagonal matrix that contains the *singular values* of $\mathbf{D}$.

We use SVD in our analysis because it provides a method to investigate the information content of our observables and their impact on each of the parameters. Equations (3) and (4) were defined in terms of the observed or expected error so SVD can be used to study various properties of $\mathbf{D}$:

- The expected uncertainties in each of the parameters via the covariance matrix

$$C_{jk} = \sum_{i=1}^N \frac{V_{ji}V_{ki}}{W_{ii}^2}, \quad (6)$$

- The significance of each of the observables for the determination of the parameter solution

$$S_i = \left(\sum_{j=1}^N U_{ij}^2 \right)^{1/2}. \quad (7)$$

2.2. Parameters & Observables

For this study we need to distinguish clearly between our parameters and observables. The *parameters* are the input ingredients $\mathbf{x}$ to our physical model. For example in a stellar code the parameters include mass, age and chemical composition. The *observables* $\mathbf{f}$ are then the outputs of the models given these $\mathbf{x}$ and are those things that we can normally measure, such as magnitudes, effective temperature and oscillation frequencies. To refrain from ambiguity between the observable errors and the uncertainties in the parameters we shall denote the former by ϵ and the latter by σ .

2.2.1. Parameters & Models

We describe a solar-type star with five adjustable parameters. These are mass M , age (or evolutionary stage) τ , chemical composition given by two of (X, Y, Z) where $X + Y + Z = 1$ and X , Y and Z are the initial hydrogen, helium and metal abundance respectively, and the mixing-length parameter α which describes convection in the outer envelope of the star.

We use the *Aarhus STellar Evolution Code* (ASTEC) for stellar structure and evolution and the *ADiabatic PuLSation* code (ADIPLS) to calculate non-radial oscillation frequencies (Christensen-Dalsgaard 1982). For each model evolved with the parameters (M, τ, X, Z, α) ASTEC produces stellar quantities which are then used to calculate the oscillation frequencies with ADIPLS. The outputs from the models implemented in this work are the global structure parameters such as radius R_* , effective temperature T_{eff} , and a set of oscillation frequencies for $l = 0, 1, 2, 3$ and $n = 1, 2, \dots, 32$. The Basel model atmospheres (Lejeune et al. 1997) are used to calculate magnitudes and colors. R_* , T_{eff} , $\log g$, and $[Z/X]$ are used to obtain spectra which are then integrated in a range of wavelengths to produce magnitudes.

We fixed the physics of the stellar evolution models. The equation of state (EOS) is that of Eggleton, Faulkner & Flannery (1973). The opacities are the OPAL 1995 tables (Iglesias & Rogers 1996), supplemented by Kurucz opacities at low temperatures. Convection is described by the classical *mixing-length theory* (Böhm-Vitense 1958) where the mixing-length ℓ is defined as $\ell = \alpha H_p$, α is

the free *mixing-length parameter* and H_p is the local pressure scale height. Diffusion is not included and so we allow $[M/H] \sim [Fe/H]$ to estimate $[Z/X]$ where we are assuming a near solar-composition. We ignore overshoot effects and do not include Coulomb corrections. This study concentrates on one main-sequence model star with solar-type oscillations whose parameters are given in Table 1 but is extendable to a solar-type star with similar characteristics.

2.2.2. Observables

Typical observables for such a star come from various sources of observations. Spectroscopy provides effective temperature T_{eff} , gravity $\log g$ and metallicity $[M/H]$ measurements. With photometry we obtain magnitudes e.g. V and colors e.g. $(U - V)$. Oscillation frequencies are obtained using time-series observations of photometric and/or spectroscopic origin. Interferometry measures a limb-darkened¹⁰ stellar angular diameter in milliarcseconds (mas) and this coupled with a parallax gives an absolute diameter value (we use the radius R_* value for this work).

The observables O_i and expected errors ϵ_i for our model star are given in Table 2. The measurement errors reflect what is most currently quoted in the literature. However we do realize that some of these values are optimistic, and are unlikely to be improved upon. In this way, we can investigate how much further interferometry and asteroseismology can take us for determining stellar mass.

We used frequency separations $\Delta\nu_{n,l}$ and $\delta\nu_{n,0}$ instead of individual frequencies $\nu_{n,l}$ where

$$\Delta\nu_{n,l} = \nu_{n,l} - \nu_{n-1,l}, \quad (8)$$

$$\delta\nu_{n,0} = \nu_{n+1,0} - \nu_{n,2}. \quad (9)$$

While we realize that we are throwing away important information, the reasons for doing this are justified: the high sensitivity of the frequency values to changes in the parameters (non-linearity of the problem), and the unreliability of the treatment of the stellar surface layers and hence absolute values of $\nu_{n,l}$.

We also assume that we can identify the (l, n) quantum numbers. Rotation will induce a small effect (solar-type star) so we can assume $(l, m) \sim (l, m = 0)$. The degree l can be interpreted by using echelle-diagrams (see Figure 6 in Kjeldsen et al. (2005)). It is only the radial order n that is then difficult to identify. This number is model-dependant, and there is no direct way of *observing* it. However with a rich frequency spectrum expected of these stars, the relative n position of each mode of degree l can be identified and then also the average frequency separations $\bar{\Delta\nu}$ and $\bar{\delta\nu}$ (independent of n). These observables are used for the initial fitting process, and an inspection of the $\nu_{n,l}$ that come from the models allows an n identification to ± 1 .

3. VARIOUS ROLES OF THE OBSERVABLES

Why should a diameter measurement such as that expected from interferometry be important? This section highlights the importance that a radius measurement has when coupled with various observables and different measurement errors.

3.1. Significance

The observables play very different roles in the determination of the parameter solution depending on which combination of observables (O_i) are available and the size of their measurement errors (ϵ_i). Using equation (7) we calculated the significance of some observables $S(O_i)$ using different observable combinations.

Figure 1 (top panel) illustrates the importance of some typical observables in the absence of a radius measurement and oscillation frequencies. The ϵ_i are those quoted from Table 2. While this figure is mainly for comparison with the lower panel we highlight a few points: the photometric observables appear to supply more information than the spectroscopic — this is contrary to what is often believed. For example, the colors are more significant than T_{eff} . $S([M/H]) \sim 0.85$ where we may have assumed that most information about chemical composition comes from $[M/H]$ and so should be ~ 1 . Also note the high values of both $S(\log g)$ and $S(V)$. They are responsible for determining both the radius and the mass of the star.

We then included R_* , two $\Delta\nu_{n,l}$ and one $\delta\nu_{n,0}$ in the previous set of observables. Figure 1 (lower panel) illustrates how the relative information content in each O_i changes. There are two notable changes: (1) $\log g$ and V contain almost no information while both the observed R_* and $\Delta\nu_{n,l}$ become responsible for determining the true radius (and mass) of the star, (2) $S(V - R)$ and $S([M/H])$ decrease by a small amount indicating that the information from colors and metallicity is not contained in the new observables. We believe this information is primarily the chemical composition. This implies that either colors or a metallicity are important observables to have when complementing seismic and radius measurements. We also note that while $S(V - R)$ decreases by $> 25\%$, $S(U - V)$ remains the same.

We included more than one $\Delta\nu_{n,l}$ to highlight how when we change the measurement errors, the information contained in one observable is passed to another, in particular, between R_* and $\Delta\nu_{n,l}$. If we had included just one $\Delta\nu_{n,l}$, then $S(\Delta\nu_{n,l}) \sim S(\delta\nu_{n,0}) \sim 1$. When there are two observables contributing similar (but not the same) information, the content gets spread among them. Similarly, with three $\Delta\nu_{n,l}$, $S(\Delta\nu_{n,l}) \sim 0.55$. Figure 2 illustrates this. $S(\Delta\nu_{n,l})$ (bold dashed line) and $S(R_*)$ (bold continuous lines) are shown as a function of $\epsilon(R)$ with $\epsilon(\nu) = 0.5 \mu\text{Hz}$. At the smallest $\epsilon(R)$, $S(R_*) \sim 1$. Increasing $\epsilon(R)$ causes $S(R_*)$ to decrease, while $S(\Delta\nu_{n,l})$ increases because it is taking over its role. The non-bold lines show the same but for $\epsilon(\nu) = 1.3, 2.5 \mu\text{Hz}$. There is a similar but slower trend, because the radius remains more important than $\Delta\nu_{n,l}$ even for higher values of $\epsilon(R)$. Using only one $\Delta\nu_{n,l}$ would not show an increase in $S(\Delta\nu_{n,l})$ because it would be already near 1, but $S(R_*)$ would decrease more slowly, while observables such as $\log g$ and V would increase in importance.

Both Figures 1 and 2 show that the relative importance of observables depends not only on the individual ϵ_i but also on the combination of O_i available, and that there is no straightforward relationship between a set of O_i and the parameters they are responsible for constraining.

3.2. Parameter Correlations

¹⁰ Information regarding the light intensity profile across the star is provided by the interferometric observations of the *second lobe of the visibility function*. In the case where the star is not fully resolved, i.e. we only get some visibility points on the first lobe, then we require a limb-darkened model for the star, rendering R_* model-dependent. The limb-darkened profile also varies if we use 1-D or 3-D atmospheric models. Both Aufdenberg et al. (2005) and Bigot et al. (2006) provide detailed and quantitative descriptions on this matter and also confirm the inadequacy of the 1-D models in reproducing these second-lobe measurements.

The combination of observables we use is important for the independence of the parameters. In general, there should be a unique set of frequencies for every possible combination of (M, τ, X, Z, α) . However, we are not using individual $\nu_{n,l}$ but frequency separations for the reasons explained in Section 2.2.2. This creates some dependencies among the parameters such as that between M and τ , M and α and M and X . With the addition of measurement errors, this degeneracy between different parameter combinations becomes worse.

To illustrate some of the dependencies among the parameters, we calculated χ^2 surfaces for two parameters p and q while keeping the other parameters fixed at their correct values. We evaluate 68.3%, 90% and 99% confidence levels as defined for a two-dimensional χ^2 i.e. $\Delta\chi_r^2 = \chi_{min}^2 - \chi_{pq}^2 = [2.31, 4.61, 9.21]$. We used $\epsilon(R) = 0.01 R_\odot$ and $\epsilon(\nu) = 1.3\mu\text{Hz}$ and defined $\chi_r^2 = \chi^2 / (\#observables - 2)$.

Using a set of $\nu_{n,l}$ as observables the 99% confidence region encircled the correct parameter values to within less than 1% of each of the corresponding parameters (it produced almost a dot centered on its true value), supporting the idea that each set of parameters should produce a unique set of $\nu_{n,l}$.

To show an example of the dependencies introduced by using the frequency separations, Figure 3 illustrates the correlated χ^2 surface for mass and α while holding (τ, X, Z) fixed at their true values using OS3 (see section 3.3). Clearly for any value of M there is a corresponding α that will give a minimum χ^2 value. We hope that a minimization will lead to accurate values, but we may need additional observables to help constrain the solution.

3.3. Propagated errors

Can we get a precise determination of the mass using a radius measurement? How well do we need to know our observables? Will the effort of obtaining an interferometric diameter be outweighed by the benefits, or can some other observable produce a similar result?

To answer these questions, we investigated the expected parameter uncertainties through equation (6) for various observables with different errors. For the remainder of this paper we shall discuss three sets of observables:

$$\text{OS1} = \{R_\star, T_{\text{eff}}, [M/H], \bar{\Delta\nu}, \bar{\delta\nu}\},$$

$$\text{OS2} = \{R_\star, T_{\text{eff}}, [M/H], \Delta\nu_{n,l}\}$$

and

$$\text{OS3} = \{R_\star, T_{\text{eff}}, [M/H], \Delta\nu_{n,l}, \delta\nu_{n,l}\}$$

for $n = 9, 10, \dots, 27$ and $l = 0, 1, 2$. For OS2 and OS3 we include a total of 21 large frequency separations, where we have assumed that we cannot identify every consecutive mode for each l and thus have even fewer frequency separations. For OS3 we also include 5 small frequency separations. We remind readers that the parameter uncertainty is denoted by σ while the measurement errors are denoted by ϵ .

For ease of reading we shall refer to $\epsilon(\nu) = 0.5\mu\text{Hz}$ as LN and $1.3\mu\text{Hz}$ as HN. Figure 4 shows the theoretical uncertainties on each of the parameters as a function of $\epsilon(R)$. We show results using LN (black) and HN (gray). The dashed lines show the results for OS1. The continuous lines show OS2, and the dotted lines show OS3.

For all parameters we find that $\sigma(P)$ (parameter uncertainty) is a function of $\epsilon(R)$ for all combinations of observables. We

also see that for M , X and Z the different observable combinations and errors do not impact significantly the theoretical uncertainties for $\epsilon(R) \leq 3\%$. Only for τ and α , using OS2 instead of OS1 may not always be beneficial. This is because $\delta\nu$ is excluded from OS2 and this observable is essential for determining τ and, as it turns out, α too.

- **Mass:** Whatever combination we choose, we find that for $\epsilon(R) \leq 3\%$ $\sigma(M)$ does not change. A radius measurement will always be more important than seismic information once we reach a precision of this order. As the radius error begins to increase, its relative weight for mass determination decreases, while the relative weight of the seismic information increases. The quantitative differences between using LN and HN for each observable combination for $\epsilon(R) \geq 3\%$ supports the idea that seismic information is the dominant contributor to the reduction of the uncertainty in mass at higher $\epsilon(R)$.
- **Age:** Either a reduction in frequency error or an increase in observables significantly affects $\sigma(\tau)$. OS1 and OS3 do not benefit significantly from the radius measurement, but both produce better constraints on the age than OS2. This is precisely because they contain $\delta\nu$ which is fundamental in constraining this parameter. However, for OS2 a precise radius measurement reduces $\sigma(\tau)$ by 200% for LN and HN. The lack of the observable $\delta\nu$ forces $R_\star$ to constrain the age. Not surprisingly, we find that if we use LN instead of HN for all observable combinations there is a large improvement in $\sigma(\tau)$.
- **X:** Adding observables and obtaining smaller frequency errors leads to subtle differences in $\sigma(X)$ for low radius error. OS1 with either LN or HN produce very similar constraints on X . Using OS2 does not change $\sigma(X)$ very much for $\epsilon(R) \leq 3\%$. At larger values, we find that the additional large frequency separations (especially for LN) constrain X to about 10%, an improvement of a factor of 2 over HN. OS3+HN and OS2+LN produce similar results, indicating that it is not the presence of $\delta\nu$ specifically that is important, just the addition of (seismic) observables.
- **Z:** This is one of the parameters that is least influenced by either radius or seismic observables. It is mainly constrained by $[M/H]$, but because this implies knowing X , other observables play a role in constraining this parameter. Radius is most important for Z when we use OS1, because we have less information available. Using OS2 and OS3 decreases the dependence of Z on $R_\star$. In fact, with OS3+LN, we find that the radius has almost no role in constraining Z . For Z , the radius is important only when there is not enough information available. As we increase the number of seismic observables, this information supercedes the role of the radius. We also find that whatever combination we use, $\sigma(Z)$ never decreases below 10% even using LN.
- **α :** The determination of α seems to be more complex than the determination of any other parameter. In general, the addition of observables (in number) coupled with better frequency errors leads to lower parameter uncertainties. This is not always the case for α . OS2 is least influenced by a reduction in radius error. In fact, we find for HN, OS1 gives better constraints on α than

OS2 for $\epsilon(R) \leq 4\%$. Only when an observable set contains the small frequency separation and for small values of radius error, do we get a significant decrease in the theoretical uncertainty in α . Using LN instead of HN always affects the determination of $\sigma(\alpha)$, but more so for OS2 when the radius information is less important than the frequency information.

The role of the radius sometimes depends on what other information is available. For example, if we seem to be *missing* information, then improving the radius error will lead to a corresponding reduction in the uncertainty of some parameter, like Z . The determination of α shows an interesting trend. A precise radius determination *complements* precise frequencies. Either of these alone does improve the uncertainty, but both together have a larger impact on $\sigma(\alpha)$. Clearly for $\epsilon(R) < 3\%$ the choice of observable set does not change $\sigma(M)$; it is R_* which dominates the mass determination.

3.4. Magnitude versus Radius

Are these uncertainty values worth the observing time? We compared the propagated error using OS2 with M_V (magnitude) instead of R_* (radius) to see whether M_V could produce results similar to R_* . M_V is the only other measurement that might constrain the mass as R_* does.

Figure 5 shows $\sigma(M)$ as a function of both $\epsilon(R)$ (continuous lines) and $\epsilon(M_V)$ (dashed lines) for two $\epsilon(T_{\text{eff}}) = [50, 230\text{K}]$ for LN (left panel) and HN (right panel). We have attempted to scale the expected errors on both observables so that the quoted errors are comparable in terms of measurement difficulty. We chose $\epsilon(R) = 0.01 R_\odot$ ($\sim 1\%$) to be similar to $\epsilon(M_V) = 0.05$ mag. For both cases $\sigma(M)$ using M_V will never reach the precision that a radius measurement allows. The smallest mass uncertainty using M_V is $\sim 5\%$, while if we use R_* it reaches below 1% . Also M_V needs to be complemented with other good observables such as T_{eff} and LN to get this precision, whereas R_* is a completely independent measurement that does not need the help of other observables. These are two very clear reasons for choosing to obtain an interferometric measurement of diameter. For HN (right panel) it is even clearer that R_* is most important.

Even if our scaling is incorrect for the comparison of magnitude and radius errors, it is unlikely that an M_V measurement will have a precision of better than 0.05 mag, in which case the smallest mass uncertainty is really above 7% .

4. SIMULATIONS

To test the validity of the theoretical results presented in Section 3.3 we performed simulations and tried to fit the observables to recover the input parameters. Part of this work also involved finding a reliable method to apply to any set of observables so that we could successfully estimate the parameters of the star within the theoretical uncertainties. We use two methods: direct inversions and minimizations. The direct inversions provide a test for the linear approximation of equation (1) by using an initial guess of the parameters $\mathbf{x}_0$ and equation (2). We did this only for OS1. Minimizations iteratively incorporate a modified version of equation 2 (Levenberg-Marquardt algorithm) and were performed with OS1, OS2 and OS3.

The observables $\mathbf{O} = \{R_o, T_o, [M/H]_o, \nu_{(n,l)o}\}$ were simulated as follows:

$$R_o = R_r + r_g \epsilon(R) \quad (10)$$

$$T_o = T_r + r_g \epsilon(T) \quad (11)$$

$$[M/H]_o = [M/H]_r + r_g \epsilon([M/H]) \quad (12)$$

$$\nu_{io} = \nu_{ir} + r_g \epsilon(\nu) + \left(\frac{\nu_i}{\nu_0} \right)^2 \quad (13)$$

where $R = R_*$; $T = T_{\text{eff}}$; the subscript 'o' denotes the simulated *observed* value; the subscript 'r' denotes the real value that comes directly from the stellar code; the ν_i are individual frequencies; r_g is a random Gaussian error for each observable with $\sigma = 1$; ν_0 is an arbitrary reference frequency value, which was chosen to be $6000\mu\text{Hz}$. Using these simulated frequencies we calculated each of the $\Delta\nu_{n,l}$ and $\delta\nu_{n,0}$ from equations (8) and (9). Table 2 provides the errors, and $\epsilon(\Delta\nu_{n,l}) = \epsilon(\delta\nu_{n,0}) = \sqrt{2\epsilon(\nu_{n,l})^2}$.

4.1. Linear Approximation -vs- Minimizations for OS1

Direct inversions will allow us to investigate the natural weight that R_* and its error have on the determination of M , because we do not use a minimization algorithm but just the linear approximation and equation (2). For each radius and frequency error, we generated a total of 100 simulations of the observables. We obtained a list of $\mathbf{x}_0$ from a grid of models (Section 4.2.1) and chose the first set from this list to be the initial guess. For most of the simulations, an initial mass of $\sim 0.9M_\odot$ was used (the real value = 1.03). The system is relatively linear in these parameters and observables hence the inversion results should be independent of the initial values. (This was tested, and the results varied to less than 1% .) The simulations were repeated for various frequency and radius errors.

Figure 6 shows the mean and standard deviation of the inverted (*fit*) mass from the simulations as a function of the radius error. The dotted line shows the real mass value. Each panel corresponds to a different $\epsilon(\nu)$. The upper panel shows LN, the center HN and the lower panel has $\epsilon(\nu) = 2.5\mu\text{Hz}$. The envelope dashed lines show the theoretical uncertainties.

Figure 6 (top and center panels) shows that the mass uncertainty is a clear linear function of the error in radius. In fact, $\epsilon(\nu)$ has a very modest effect on both the precision and the accuracy of the mass. For the two upper panels, there is no apparent difference, indicating that the radius primarily determines the mass. However at $\epsilon(\nu) = 2.5\mu\text{Hz}$ we do see an effect on both the precision *and* the accuracy of the results. This appears to be a side effect of poorly constraining the other parameters, which indirectly leads to incorrect mass estimates.

It is encouraging to find that the simulation results are consistent with theory *and* that we can safely estimate the mass to within its theoretical uncertainty. Unfortunately for $\epsilon(R) = 5\%$, *safely* estimating the mass to within 20% may not be very useful. However, we do find that for $\epsilon(R) \leq 2\%$ we are capable of determining the mass better than the theoretical uncertainty and quite accurately (for the two smaller frequency errors). For all simulation results, the true mass value always falls within 1 standard deviation of the fit mass.

For the other parameters, the theoretical predictions are consistent with the simulation results. Figure 7 shows the mean and the standard deviation of the inverted (*fit*) age. As expected, the size of the frequency error is very important, especially for OS1. $\epsilon(R)$ does have a modest effect and is most noticeable for LN (top panel).

To test whether a minimization algorithm improves the uncertainties on the parameters, we repeated the simulations and

then fit for the parameters (using the minimizing method) for a range of radius errors and LN. Figure 8 shows the standard deviations of the fit parameters, (for age we show $\sigma(\tau)/4$). All of the parameter's real values were within the σ shown in this figure.

The precision of the parameters are better than the theoretical ones (Figures 4,8). There is a clear dependence of the uncertainties on the radius error when $\epsilon(R) < 3\%$. Unlike the theoretical uncertainties, for larger $\epsilon(R)$ there is no significant degradation in the precision of the parameters. This uncertainty-error dependence changes drastically for larger $\epsilon(R)$ because the minimization method is forcing a balance between the errors and the observations, unlike when we use the simple linear approximation (Equation 2).

4.2. Simulations and Minimizations with OS2 and OS3

Since we are introducing more frequency observables in OS2 and OS3, we are effectively giving less weight to the radius measurement for constraining the parameters. The fit parameters are thus more sensitive to the initial parameter estimates. It is therefore necessary to use small grids of models to obtain a good initial guess, and then let the minimization algorithm fit all of the observables.

4.2.1. Model Grids

We created grids of models that span the five dimensional model space over a range of values that encompass about 10-30% on either side of the parameter values given in Table 1. These values covered $0.95 \leq M \leq 1.09 M_\odot$, $0.1 \leq \tau \leq 2.0$ Gyr, $0.68 \leq X \leq 0.76$, $0.014 \leq Z \leq 0.022$ and $1.2 \leq \alpha \leq 1.8$. We divided each of the parameter ranges into five (ten for mass), and calculated models for each of these points, and then interpolated only along the mass for a much finer grid. We are restricting the range in mass, age and Z , but we assume that we can constrain the parameters within this range from the observables.

We later extended the mass range to be between 0.75 and $1.20 M_\odot$ to investigate whether our original parameter range was too restricted. Using $\tau = 0.1$, $X = 0.70$, $Z = 0.024$, $\alpha = 1.5$ and varying mass, we used the grids to see how well we could recover the mass in this extended mass range. These parameters were chosen to test for any biases introduced by selecting our original ranges to be nearly symmetric about the correct values. We tested this for $\epsilon(R) = 0.02 R_\odot$ and HN only. There were 100 simulations for each mass.

We searched through the grids to find all of the parameter combinations that reproduced R_* and $\Delta\nu$ to within $\pm 3\epsilon$. We discarded the combinations with χ^2 larger than 1, and adopted the mean value of each parameter from the remaining combinations to be the *fit* values. We later used them as the initial parameter values for the minimization. Figure 9 shows the mean of the simulations $\pm 3\sigma$ where σ is the standard deviation of each group of simulations. The dotted line indicates the ideal position for the mean of the simulation results. While there seems to be some systematic offset as a function of mass, in most cases the 3σ crosses the correct value. For the other parameters, the fit values are not as well determined (we haven't interpolated for them). This appears to be responsible for the offset in fit mass.

4.2.2. Results of Minimizations

Initial estimates of the parameters were obtained from the model grids. We added a constant of 0.02 to the initial estimate of X for two reasons: 1) X had always shown a systematic offset when using the model grids and, 2) if the value of χ^2 from our initial estimates is too low, the minimization algorithm may not search among all possible solutions. We then allowed the code to minimize in all available observables. The solution usually converged within four iterations. We set the χ_r^2 tolerance level to be 0.1, where χ^2 is calculated from equation (5), but we used 3ϵ errors for the process instead of 1ϵ , and $\chi_r^2 = \chi^2/n$ where n is the number of degrees of freedom. An ideal value of χ_r^2 is 1. Anything much larger implies a bad fit, an error in the physics, or incorrectly quoted errors.

$\epsilon(R)$ took values from $0.001-0.05 R_\odot$ ($\sim 0.1 - 6.0\%$). $\epsilon(\nu)$ took values of 0.5 (LN) and $1.3 \mu\text{Hz}$ (HN). Figure 10 shows the mean and standard deviation (1σ) of the fit mass as a function of $\epsilon(R)$ for OS2+HN. The dotted line is the true mass value. We show only this combination because those for LN¹¹ and those using OS3 did not lead to a significant difference, except for τ and α whose uncertainties are represented by the dashed lines in Figure 11.

Our global results show that for all of the parameters 1) the mean values fit to within 1σ of the correct value (Figure 10 shows this for M only). 2) The parameter uncertainties are smaller than those predicted by theory. This is highlighted in Figure 11. 3) All of the uncertainties show some dependence on $\epsilon(R)$.

Mass is the parameter that is most affected by an improvement in the precision of R_* . Figure 10 shows the mean and standard deviation of the fit mass. $\sigma(M)$ is clearly dependent on $\epsilon(R)$ for $< 3\%$ errors. If we reach 0.1% in radius error, then we can determine the mass to better than 1%. For $\epsilon(R) > 3\%$, $\sigma(M)$ does not change significantly. This can be seen more clearly in Figure 11. For $\epsilon(R) < 3\%$, there is little difference between the uncertainties arising from the minimizations (and more observables) or the linear approximation with 5 observables (Figures 6,8). This can be understood by considering that for small radius errors, this observable has such a large weight that it determines uniquely the mass value. In this regime, the different combinations of observables do not have any influence, just as the theoretical uncertainties showed (Figure 4 top panel). So whether we use a minimization method with 26 observables or a direct inversion with only 5 observables, having a well measured radius will uniquely determine the mass. When the relative weight of the radius decreases, i.e. its error increases, other observables begin to play a role. This is why we see a dramatic change in the mass uncertainty between using OS1, OS2 and OS3 when $\epsilon(R) > 3\%$ (Figures 6,10).

Figure 11 shows the standard deviations for all of the parameters. The dashed lines represent the results for OS3+LN and the dotted line for OS3+HN (continuous are OS2+HN). For M , X , and Z the results did not change significantly.

- The top panel illustrates $\sigma(\tau)$. The values are rather high, but the standard deviations that result from a star of 4 Gyr (instead of 1 Gyr) have similar absolute values and thus much smaller relative values. Note the qualitative differences between the set of observables with $\delta\nu$ (dashed and dotted lines) and the set without (continuous line). Even if we use 21 large frequency separations with the precision of LN, we do not get the same age uncertainty as when we use OS3.

¹¹ Extending the radius error to $0.001 R_\odot$ did produce a small improvement in the parameters at this level for LN.

This demonstrates that $\delta\nu$ is crucial for obtaining a precise determination of the age (or stellar evolutionary stage) (e.g. Brown et al. (1994); Brown (1994); Miglio & Montalbán (2005); Mazumdar (2005)). For $\epsilon(R) < 2\%$ we also see a slight drop in $\sigma(\tau)$. This is because for small radius errors, we get precise determinations of both M and X , so the range of possible ages that fit $\delta\nu$ is restricted, and hence we get better age determinations.

- The lower panel shows the standard deviations of all of the other parameters. Both Z and α exhibit a small $\epsilon(R)$ dependence: 9-12% for Z and 7-10% for α over the radius error range. Theory (Figure 4) predicted that $\sigma(Z)$ would never fall below 10%, and increase only slightly to 12-14% at larger radius errors. This trend is clearly consistent with the simulation results. $\sigma(\alpha)$ was predicted to be 20-22% over the range of radius error for OS2+HN and 8-14% for OS2+LN. The simulations show no significant differences between these observable combinations. For OS3+LN, theory predicted 4-12% uncertainties, comparable to the dashed line in Figure 11. $\sigma(\alpha)$ benefits significantly from the additional $\delta\nu$ reaching a precision of about 4% and slowly degrading with $\epsilon(R)$ until $\epsilon(R) = 3\%$ when it levels off at a σ value comparable to the other observable combinations. $\sigma(X)$ shows a dependence on radius error similar to $\sigma(M)$. For $\epsilon(R) \leq 3\%$ we generally estimate X to within 2-3%. For larger radius errors, $\sigma(X)$ does not increase, indicating the redundancy of a radius measurement after $\epsilon(R) = 3\%$.

While some parameters may not seem very dependent on $\epsilon(R)$, having a radius observable allows us to estimate some parameters correctly. This in turn leads to a better estimation of the other *non-radius dependent* parameters because of the more restricted acceptable range.

These results stem from an automatic method of fitting the observations. Given that there is no human input, we are confident in the results and expect that even more precise results will be possible by paying attention to each individual case, and individual observable χ^2 values.

5. CONCLUSIONS

We investigated the role that a precisely measured radius, such as that obtained through interferometry, has on the determination of the mass of a star. We also looked at how radius and oscillation frequencies work together to determine other stellar parameters.

- We found that the importance of a radius measurement depends on the combination of the available observables *and* their corresponding errors. For some typical observables such as R_* and $\Delta\nu_{n,l}$, we can expect a mass uncertainty of between 1 and 4% for $\epsilon(R)$ between 0.1 and 3% (keeping in mind that these numbers stem from an automatic parameter search and in a real case study we would pay more attention to each observable and

can expect better precision.) For $\epsilon(R) \leq 3\%$ the mass is uniquely determined by the radius observable, allowing us to use the frequencies just to probe the stellar interior.

- Our simulation errors are consistent with the theoretical errors when we use the linear approximation (Figure 6). Using a minimization method yields smaller than predicted uncertainties with similar qualitative results for all values of radius error, but particularly when $\epsilon(R) > 3\%$. For these values, the weight of the radius measurement decreases, allowing other observables to play a greater role in the determination of the parameters. The minimization method allows an optimal trade-off between all observables and their corresponding errors.
- We emphasize the importance of understanding how each observable contributes to the determination of each parameter. For example, if we want to get an estimate of Z better than 10% we need a more precise $[M/H]$. A radius measurement would not be useful. To correctly determine age (or stellar evolution stage) it is crucial to observe $\delta\nu$. Even with 21 large frequency spacings, we will not determine the age to the precision that 1 small frequency spacing will provide. It is also interesting that $\delta\nu$ coupled with a small radius error had a strong impact on the precision of the mixing-length parameter α .
- We know that a discrepancy exists between the observed and the model frequencies, which leads to a systematic offset in mass determination (e.g. Miglio & Montalbán 2005). By allowing the radius to determine the mass, we have the advantage that 1) we have an independent measurement that we can use to try to resolve the discrepancy, and 2) by using the radius to determine mass, we can use the frequencies to probe the stellar interior.
- One final remark we would like to make is how effective a radius measurement can be to detect some error in the model. During this study we conducted some *hare and hounds*¹² tests. In one particular case, we found that all of the observations were fit very well except for the radius, which showed a larger than 3ϵ deviation value. This turned out to be the result of an incorrectly quoted metallicity measurement! This just shows how powerful the radius can be to detect an error/flip, and this could possibly be used to detect a flaw in the physics of the models.

OLC would like to thank Andrea Miglio, Tim Bedding and Hans Kjeldsen for some stimulating questions. The authors are also extremely grateful for the constructive comments and suggestions given by the referee Pierre Kervella. This work was supported in part by a grant (OC) within the project POCI/CTE-AST/57610/2004 from *Fundação para a Ciência e Tecnologia* and POCI 2010 with funds from the European programme *Fundo Europeu De Desenvolvimento Regional*.

¹² Searching for model parameters when OLC is unaware of the real values.

TABLE 1
SYSTEM PARAMETERS

Parameter	Value
$M (M_{\odot})$	1.030
τ (Gyr)	1.00
X	0.740
Z	0.018
α	1.50

TABLE 2
SYSTEM OBSERVABLES

Measurement	Value (O_i)	Error (ϵ_i)
$R_{\star} (R_{\odot})$	0.946	
$T_{\text{eff}} (K)$	5421	50
$\log g$	4.5	0.3
[M/H]	0.00	0.05
M_V (mag)	4.50	0.05
(U-V) (mag)	0.633	0.005
(V-R) (mag)	0.400	0.005
$\Delta\nu$ (μHz)	148.3	
$\delta\nu$ (μHz)	14.6	
$\nu_{0.12}$ (μHz)	1996.9	

The errors on $R_{\star}$ and ν are varied.

FIG. 1.— *Top*: The significance of the observables without oscillation information and radius measurements using $\epsilon(R) = 0.01 R_{\odot}$ and $\epsilon(\nu) = 1.3 \mu\text{Hz}$. *Bottom*: The same but including oscillation and radius measurements.

FIG. 3.— χ^2 contour plot for M and α . (X, Z, τ) are fixed at their correct value. We used OS3 (see Section 3.3) with $\epsilon(R) = 0.02 R_{\odot}$ and $\epsilon(\nu) = 1.3 \mu\text{Hz}$ to calculate χ^2_r .

FIG. 2.— The change in the $S(R_*)$ and $S(\Delta\nu_{n,l})$ as we vary $\epsilon(R)$. $\Delta\nu_{n,l}$ increases in significance as R_* becomes more poorly constrained. Bold lines indicate $\epsilon(\nu) = 0.5 \mu\text{Hz}$, lighter lines indicate $\epsilon(\nu) = 1.3, 2.5 \mu\text{Hz}$.

FIG. 5.— Comparison of propagated mass error using either R_* (continuous) or M_V (dashed) with OS2 observables at two $\epsilon(T_{\text{eff}}) = [50, 230\text{K}]$. The left panel is that when using $\epsilon(\nu) = 0.5 \mu\text{Hz}$, the right is that for $\epsilon(\nu) = 1.3 \mu\text{Hz}$. The lower x-axis shows $\epsilon(R)$ in appropriate units whereas the upper x-axis shows what we could consider a comparative $\epsilon(M_V)$.

FIG. 4.— Comparison of the expected theoretical uncertainties between OS1 (dashed), OS2 (continuous) and OS3 (dotted) observable sets and different frequency errors for all parameters as a function of $\epsilon(R)$. Results for HN are shown by the gray line, and those for LN are represented by the black lines (darker lines = smaller frequency error).

FIG. 6.— Mean and standard deviation of the fit (*inverted*) mass for the simulations as a function of $\epsilon(R)$ using OS1. *Upper* Results for LN; *Center* Results for HN; *Lower* Results for $\epsilon(\nu) = 2.5 \mu\text{Hz}$.

FIG. 7.— Similar to Figure 6, but for age.

FIG. 8.— Parameter uncertainties as a function of $\epsilon(R)$ determined from the minimizations using OS1+LN.FIG. 9.— Mean and 3σ uncertainty of the fit mass as a function of the true mass value resulting from the simulations using only the model grids. Dashed vertical lines indicate boundary of extrapolated and evaluated models.FIG. 10.— Mean and 1σ standard deviation of the minimizations for the fit mass using OS2+HN as a function of $\epsilon(R)$.

FIG. 11.— Comparison of standard deviations of all of the fit parameters as a function of $\epsilon(R)$. OS2+HN, OS3+LN and OS3+HN (τ only) are denoted by the solid, dashed and dotted lines respectively.
